# Inference in Bayesian Networks 

Andrea Passerini<br>passerini@disi.unitn.it

Machine Learning

## Inference in graphical models

## Description

- Assume we have evidence $\mathbf{e}$ on the state of a subset of variables $E$ in the model (i.e. Bayesian Network)
- Inference amounts at computing the posterior probability of a subset $\boldsymbol{X}$ of the non-observed variables given the observations:

$$
p(\boldsymbol{X} \mid \boldsymbol{E}=\mathbf{e})
$$

## Note

- When we need to distinguish between variables and their values, we will indicate random variables with uppercase letters, and their values with lowercase ones.

## Inference in graphical models

## Efficiency

- We can always compute the posterior probability as the ratio of two joint probabilities:

$$
p(\boldsymbol{X} \mid \boldsymbol{E}=\mathbf{e})=\frac{p(\boldsymbol{X}, \boldsymbol{E}=\mathbf{e})}{p(\boldsymbol{E}=\mathbf{e})}
$$

- The problem consists of estimating such joint probabilities when dealing with a large number of variables
- Directly working on the full joint probabilities requires time exponential in the number of variables
- For instance, if all $N$ variables are discrete and take one of $K$ possible values, a joint probability table has $K^{N}$ entries
- We would like to exploit the structure in graphical models to do inference more efficiently.

## Inference in graphical models

## Inference on a chain (1)

$$
p(\mathbf{X})=p\left(X_{1}\right) p\left(X_{2} \mid X_{1}\right) p\left(X_{3} \mid X_{2}\right) \cdots p\left(X_{N} \mid X_{N-1}\right)
$$

- The marginal probability of an arbitrary $X_{n}$ is:

$$
p\left(X_{n}\right)=\sum_{X_{1}} \sum_{X_{2}} \cdots \sum_{X_{n-1}} \sum_{X_{n+1}} \cdots \sum_{X_{N}} p(\mathbf{X})
$$

- Only the $p\left(X_{N} \mid X_{N-1}\right)$ is involved in the last summation which can be computed first, giving a function of $X_{N-1}$ :

$$
\mu_{\beta}\left(X_{N-1}\right)=\sum_{X_{N}} p\left(X_{N} \mid X_{N-1}\right)
$$

## Inference in graphical models

## Inference on a chain (2)

- the marginalization can be iterated as:

$$
\mu_{\beta}\left(X_{N-2}\right)=\sum_{X_{N-1}} p\left(X_{N-1} \mid X_{N-2}\right) \mu_{\beta}\left(X_{N-1}\right)
$$

down to the desired variable $X_{n}$, giving:

$$
\mu_{\beta}\left(X_{n}\right)=\sum_{X_{n+1}} p\left(X_{n+1} \mid X_{n}\right) \mu_{\beta}\left(X_{n+1}\right)
$$

## Inference in graphical models

## Inference on a chain (3)

- The same procedure can be applied starting from the other end of the chain, giving:

$$
\mu_{\alpha}\left(X_{2}\right)=\sum_{X_{1}} p\left(X_{1}\right) p\left(X_{2} \mid X_{1}\right)
$$

up to $\mu_{\alpha}\left(X_{n}\right)$

- The marginal probability is now computed as the product of the contributions coming from both ends:

$$
p\left(X_{n}\right)=\mu_{\alpha}\left(X_{n}\right) \mu_{\beta}\left(X_{n}\right)
$$

## Inference in graphical models

## Inference as message passing

- We can think of $\mu_{\alpha}\left(X_{n}\right)$ as a message passing from $X_{n-1}$ to $X_{n}$

$$
\mu_{\alpha}\left(X_{n}\right)=\sum_{X_{n-1}} p\left(X_{n} \mid X_{n-1}\right) \mu_{\alpha}\left(X_{n-1}\right)
$$

- We can think of $\mu_{\beta}\left(X_{n}\right)$ as a message passing from $X_{n+1}$ to $X_{n}$

$$
\mu_{\beta}\left(X_{n}\right)=\sum_{X_{n+1}} p\left(X_{n+1} \mid X_{n}\right) \mu_{\beta}\left(X_{n+1}\right)
$$

- Each outgoing message is obtained multiplying the incoming message by the "local" probability, and summing over the node values

## Inference in graphical models

## Full message passing

- Suppose we want to know marginal probabilities for a number of different variables $X_{i}$ :
(1) We send a message from $\mu_{\alpha}\left(X_{1}\right)$ up to $\mu_{\alpha}\left(X_{N}\right)$
(2) We send a message from $\mu_{\beta}\left(X_{N}\right)$ down to $\mu_{\beta}\left(X_{1}\right)$
- If all nodes store messages, we can compute any marginal probability as

$$
p\left(X_{i}\right)=\mu_{\alpha}\left(X_{i}\right) \mu_{\beta}\left(X_{i}\right)
$$

for any $i$ having sent just a double number of messages wrt a single marginal computation

## Inference in graphical models

## Adding evidence

- If some nodes $\mathbf{X}_{e}$ are observed, we simply use their observed values instead of summing over all possible values when computing their messages

## Example

$$
p(\mathbf{X})=p\left(X_{1}\right) p\left(X_{2} \mid X_{1}\right) p\left(X_{3} \mid X_{2}\right) p\left(X_{4} \mid X_{3}\right)
$$

- The marginal probability of $X_{2}$ and observations $X_{1}=x_{e_{1}}$ and $X_{3}=x_{e_{3}}$ is:

$$
\begin{aligned}
p\left(X_{2}, X_{1}=x_{e_{1}}, X_{3}=\right. & \left.x_{e_{3}}\right)=p\left(X_{1}=x_{e_{1}}\right) p\left(X_{2} \mid X_{1}=x_{e_{1}}\right) . \\
& \cdot p\left(X_{3}=x_{e_{3}} \mid X_{2}\right) \sum_{X_{4}} p\left(X_{4} \mid X_{3}=x_{e_{3}}\right)
\end{aligned}
$$

## Computing conditional probability given evidence

- When adding evidence, the message passing procedure computes the joint probability of the variable and the evidence, and it has to be normalized to obtain the conditional probability given the evidence:

$$
p\left(X_{n} \mid \boldsymbol{X}_{e}=\mathbf{x}_{e}\right)=\frac{p\left(X_{n}, \boldsymbol{X}_{e}=\mathbf{x}_{e}\right)}{\sum_{X_{n}} p\left(X_{n}, \boldsymbol{X}_{e}=\mathbf{x}_{e}\right)}
$$

## Inference

(a)

(b)

(c)

Inference on trees

- Efficient inference can be computed for the broaded family of tree-structured models:
undirected trees (a) undirected graphs with a single path for each pair of nodes
directed trees (b) directed graphs with a single node (the root) with no parents, and all other nodes with a single parent
directed polytrees (c) directed graphs with multiple parents for node and multiple roots, but still a single (undirected) path between each pair of nodes

## Factor graphs

## Description

- Efficient inference algorithms can be better explained using an alternative graphical representation called factor graph
- A factor graph is a graphical representation of a graphical model highlighting its factorization (i.e. conditional probabilities)
- The factor graph has one node for each node in the original graph
- The factor graph has one additional node (of a different type) for each factor
- A factor node has undirected links to each of the node variables in the factor

## Factor graphs: examples

$p(x 3 \mid x 1, x 2) p(x 1) p(x 2)$

$f(x 1, x 2, x 3)=p(x 3 \mid x 1, x 2) p(x 1) p(x 2)$

$\mathrm{fc}(\mathrm{x} 1, \times 2, \times 3)=p(\times 3 \mid \times 1, \times 2)$
$\mathrm{fa}(\times 1)=p(\times 1)$
$\mathrm{fb}(\times 2)=p(\times 2)$

$$
\mathrm{fa}(\mathrm{x} 1)=\mathrm{p}(\mathrm{x} 1)
$$

$$
\mathrm{fb}(\mathrm{x} 2)=\mathrm{p}(\mathrm{x} 2)
$$

## Inference

The sum-product algorithm

- The sum-product algorithm is an efficient algorithm for exact inference on tree-structured graphs
- It is a message passing algorithm as its simpler version for chains
- We will present it on factor graphs, assuming a tree-structured graph giving rise to a factor graph which is a tree
- The algorithm will be applicable to undirected models (i.e. Markov Networks) as well as directed ones (i.e. Bayesian Networks)

## Inference

## Computing marginals

- We want to compute the marginal probability of $X$ :

$$
p(X)=\sum_{\mathbf{X} \backslash X} p(\mathbf{X})
$$

- Generalizing the message passing scheme seen for chains, this can be computed as the product of messages coming from all neighbouring factors $f_{s}$ :

$$
p(X)=\prod_{f_{s} \in \operatorname{ne}(X)} \mu_{f_{s} \rightarrow X}(X)
$$

## Inference

$$
G_{m}\left(x_{m}, X_{s m}\right)
$$

## Factor messages

- Each factor message is the product of messages coming from nodes other than $X$, times the factor, summed over all possible values of the factor variables other than $X$ $\left(X_{1}, \ldots, X_{M}\right)$ :

$$
\mu_{f_{s} \rightarrow X}(X)=\sum_{X_{1}} \cdots \sum_{X_{M}} f_{s}\left(X, X_{1}, \ldots, X_{M}\right) \prod_{X_{m} \in \operatorname{ne}\left(f_{s}\right) \backslash X} \mu_{X_{m} \rightarrow f_{s}}\left(X_{m}\right)
$$

## Inference

Node messages

- Each message from node $X_{m}$ to factor $f_{s}$ is the product of the factor messages to $X_{m}$ coming from factors other than $f_{s}$ :

$$
\mu_{X_{m} \rightarrow f_{s}}\left(X_{m}\right)=\prod_{f_{l} \in \operatorname{ne}\left(X_{m}\right) \backslash f_{s}} \mu_{f_{l} \rightarrow X_{m}}\left(X_{m}\right)
$$

## Initialization

- Message passing start from leaves, either factors or nodes
- Messages from leaf factors are initialized to the factor itself (there will be no $X_{m}$ different from the destination on which to sum over)

- Messages from leaf nodes are initialized to 1

## Inference

## Message passing scheme

- The node $X$ whose marginal has to be computed is designed as root.
- Messages are sent from all leaves to their neighbours
- Each internal node sends its message towards the root as soon as it received messages from all other neighbours
- Once the root has collected all messages, the marginal can be computed as the product of them

## Inference

## Full message passing scheme

- In order to be able to compute marginals for any node, messages need to pass in all directions:
(1) Choose an arbitrary node as root
(2) Collect messages for the root starting from leaves
(3) Send messages from the root down to the leaves
- All messages passed in all directions using only twice the number of computations used for a single marginal

## Inference example

Consider the joint distribution as product of factors

$$
p(\mathbf{X})=f_{a}\left(X_{1}, X_{2}\right) f_{b}\left(X_{2}, X_{3}\right) f_{c}\left(X_{2}, X_{4}\right)
$$

## Inference example

## Choose $X_{3}$ as root

## Inference example

Send initial messages from leaves

$$
\begin{aligned}
& \mu_{X_{1} \rightarrow f_{a}}\left(X_{1}\right)=1 \\
& \mu_{X_{4} \rightarrow f_{c}}\left(X_{4}\right)=1
\end{aligned}
$$

## Inference example

Send messages from factor nodes to $X_{2}$

$$
\begin{aligned}
& \mu_{f_{a} \rightarrow X_{2}}\left(X_{2}\right)=\sum_{X_{1}} f_{a}\left(X_{1}, X_{2}\right) \\
& \mu_{f_{c} \rightarrow X_{2}}\left(X_{2}\right)=\sum_{X_{4}} f_{c}\left(X_{2}, X_{4}\right)
\end{aligned}
$$

## Inference example

Send message from $X_{2}$ to factor node $f_{b}$

$$
\mu_{X_{2} \rightarrow f_{b}}\left(X_{2}\right)=\mu_{f_{a} \rightarrow X_{2}}\left(X_{2}\right) \mu_{f_{c} \rightarrow X_{2}}\left(X_{2}\right)
$$

## Inference example

Send message from $f_{b}$ to $X_{3}$

$$
\mu_{f_{b} \rightarrow X_{3}}\left(X_{3}\right)=\sum_{X_{2}} f_{b}\left(X_{2}, X_{3}\right) \mu_{X_{2} \rightarrow f_{b}}\left(X_{2}\right)
$$

## Inference example

## Send message from root $X_{3}$

$$
\mu_{X_{3} \rightarrow f_{b}}\left(X_{3}\right)=1
$$

## Inference example

Send message from $f_{b}$ to $X_{2}$

$$
\mu_{f_{b} \rightarrow X_{2}}\left(X_{2}\right)=\sum_{X_{3}} f_{b}\left(X_{2}, X_{3}\right)
$$

## Inference example

Send messages from $X_{2}$ to factor nodes

$$
\begin{aligned}
& \mu_{X_{2} \rightarrow f_{a}}\left(X_{2}\right)=\mu_{f_{b} \rightarrow X_{2}}\left(X_{2}\right) \mu_{f_{c} \rightarrow X_{2}}\left(X_{2}\right) \\
& \mu_{X_{2} \rightarrow f_{c}}\left(X_{2}\right)=\mu_{f_{b} \rightarrow X_{2}}\left(X_{2}\right) \mu_{f_{a} \rightarrow X_{2}}\left(X_{2}\right)
\end{aligned}
$$

## Inference example

Send messages from factor nodes to leaves

$$
\begin{aligned}
& \mu_{f_{a} \rightarrow X_{1}}\left(X_{1}\right)=\sum_{X_{2}} f_{a}\left(X_{1}, X_{2}\right) \mu_{X_{2} \rightarrow f_{a}}\left(X_{2}\right) \\
& \mu_{f_{c} \rightarrow X_{4}}\left(X_{4}\right)=\sum_{X_{2}} f_{c}\left(X_{2}, X_{4}\right) \mu_{X_{2} \rightarrow f_{c}}\left(X_{2}\right)
\end{aligned}
$$

## Inference example

Compute for instance the marginal for $X_{2}$

$$
\begin{aligned}
p\left(X_{2}\right) & =\mu_{f_{a} \rightarrow X_{2}}\left(X_{2}\right) \mu_{f_{b} \rightarrow X_{2}}\left(X_{2}\right) \mu_{f_{c} \rightarrow X_{2}}\left(X_{2}\right) \\
& =\left[\sum_{X_{1}} f_{a}\left(X_{1}, X_{2}\right)\right]\left[\sum_{X_{3}} f_{b}\left(X_{2}, X_{3}\right)\right]\left[\sum_{X_{4}} f_{c}\left(X_{2}, X_{4}\right)\right] \\
& =\sum_{X_{1}} \sum_{X_{3}} \sum_{X_{4}} f_{a}\left(X_{1}, X_{2}\right) f_{b}\left(X_{2}, X_{3}\right) f_{c}\left(X_{2}, X_{4}\right) \\
& =\sum_{X_{1}} \sum_{X_{3}} \sum_{X_{4}} p(\mathbf{X})
\end{aligned}
$$

## Inference

## Adding evidence

- If some nodes $\mathbf{X}_{e}$ are observed, we simply use their observed values instead of summing over all possible values when computing their messages
- After normalization, this gives the conditional probability given the evidence

## Inference example

## Bayesian network

- Take a Bayesian network
- Build a factor graph representing it
- Compute the marginal for a variable (e.g. $B$ )

## Inference example

Compute the marginal for $B$

- Leaf factor nodes send messages:

$$
\begin{aligned}
& \mu_{f_{A} \rightarrow A}=P(A) \\
& \mu_{f_{D} \rightarrow D}=P(D)
\end{aligned}
$$

## Inference example

Compute the marginal for $B$

- $A$ and $D$ send messages:

$$
\begin{aligned}
\mu_{A \rightarrow f_{A, B, C}}(A) & =\mu_{f_{A} \rightarrow A}=P(A) \\
\mu_{D \rightarrow f_{C, D}}(D) & =\mu_{f_{D} \rightarrow D}=P(D)
\end{aligned}
$$

## Inference example

## Compute the marginal for $B$

- $f_{C, D}$ sends message:

$$
\mu_{f_{C, D} \rightarrow C}(C)=\sum_{D} P(C \mid D) \mu_{D \rightarrow f_{C, D}}(D)=\sum_{D} P(C \mid D) P(D)
$$

## Inference example

## Compute the marginal for $B$

- C sends message:

$$
\mu_{C \rightarrow f_{A, B, C}}(C)=\mu_{f_{C, D} \rightarrow C}(C)=\sum_{D} P(C \mid D) P(D)
$$

## Inference example

## Compute the marginal for $B$

- $f_{A, B, C}$ sends message:

$$
\begin{aligned}
\mu_{f_{A, B}, C \rightarrow B}(B) & =\sum_{A} \sum_{C} P(B \mid A, C) \mu_{C \rightarrow f_{A, B, C}}(C) \mu_{A \rightarrow f_{A, B, C}}(A) \\
& =\sum_{A} \sum_{C} P(B \mid A, C) P(A) \sum_{D} P(C \mid D) P(D)
\end{aligned}
$$

## Inference example

## Compute the marginal for $B$

- The desired marginal is obtained:

$$
\begin{aligned}
P(B) & =\mu_{f_{A, B, C} \rightarrow B}(B)=\sum_{A} \sum_{C} P(B \mid A, C) P(A) \sum_{D} P(C \mid D) P(D) \\
& =\sum_{A} \sum_{C} \sum_{D} P(B \mid A, C) P(A) P(C \mid D) P(D) \\
& =\sum_{A} \sum_{C} \sum_{D} P(A, B, C, D)
\end{aligned}
$$

## Inference

Finding the most probable configuration

- Given a joint probability distribution $p(\mathbf{X})$
- We wish to find the configuration for variables $\mathbf{X}$ having the highest probability:

$$
\mathbf{X}^{\max }=\underset{\mathbf{X}}{\operatorname{argmax}} p(\mathbf{X})
$$

for which the probability is:

$$
p\left(\mathbf{X}^{\max }\right)=\max _{\mathbf{X}} p(\mathbf{X})
$$

## Note

- We want the configuration which is jointly maximal for all variables
- We cannot simply compute $p\left(X_{i}\right)$ for each $i$ (using the sum-product algorithm) and maximize it

## Inference

The max-product algorithm

$$
p\left(\mathbf{X}^{\max }\right)=\max _{\mathbf{X}} p(\mathbf{X})=\max _{X_{1}} \cdots \max _{X_{M}} p(\mathbf{X})
$$

- As for the sum-product algorithm, we can exploit the distribution factorization to efficiently compute the maximum
- It suffices to replace sum with max in the sum-product algorithm

## Linear chain

$$
\begin{aligned}
\max _{\mathbf{X}} p(\mathbf{X}) & =\max _{X_{1}} \cdots \max _{X_{N}}\left[p\left(X_{1}\right) p\left(X_{2} \mid X_{1}\right) \cdots p\left(X_{N} \mid X_{N-1}\right)\right] \\
& =\max _{X_{1}}\left[p\left(X_{1}\right) p\left(X_{2} \mid X_{1}\right)\left[\cdots \max _{X_{N}} p\left(X_{N} \mid X_{N-1}\right)\right]\right]
\end{aligned}
$$

## Message passing

- As for the sum-product algorithm, the max-product can be seen as message passing over the graph.
- The algorithm is thus easily applied to tree-structured graphs via their factor trees:

$$
\begin{aligned}
& \mu_{f \rightarrow X}(X)=\max _{X_{1}, \ldots . X_{M}}\left[f\left(X, X_{1}, \ldots, X_{M}\right) \prod_{X_{m} \in \operatorname{ne}(f) \backslash X} \mu_{X_{m} \rightarrow f}\left(X_{m}\right)\right] \\
& \mu_{X \rightarrow f}(X)=\prod_{f_{l} \in \operatorname{ne}(X) \backslash f} \mu_{f_{l} \rightarrow X}(X)
\end{aligned}
$$

## Inference

## Recoving maximal configuration

- Messages are passed from leaves to an arbitrarily chosen root $X_{r}$
- The probability of maximal configuration is readily obtained as:

$$
p\left(\mathbf{X}^{\max }\right)=\max _{X_{r}}\left[\prod_{f_{l} \in \operatorname{ne}\left(X_{r}\right)} \mu_{f_{l} \rightarrow X_{r}}\left(X_{r}\right)\right]
$$

- The maximal configuration for the root is obtained as:

$$
X_{r}^{\max }=\underset{X_{r}}{\operatorname{argmax}}\left[\prod_{f_{l} \in \operatorname{ne}\left(X_{r}\right)} \mu_{f_{l} \rightarrow X_{r}}\left(X_{r}\right)\right]
$$

- We need to recover maximal configuration for the other variables

## Inference

## Recoving maximal configuration

- When sending a message towards $x$, each factor node should store the configuration of the other variables which gave the maximum:

$$
\phi_{f \rightarrow X}(X)=\underset{X_{1}, \ldots, X_{M}}{\operatorname{argmax}}\left[f\left(X, X_{1}, \ldots, X_{M}\right) \prod_{X_{m} \in \operatorname{ne}(f) \backslash X} \mu X_{m \rightarrow f}\left(X_{m}\right)\right]
$$

- When the maximal configuration for the root node $X_{r}$ has been obtained, it can be used to retrieve the maximal configuration for the variables in neighbouring factors from:

$$
X_{1}^{\max }, \ldots, X_{M}^{\max }=\phi_{f \rightarrow X_{r}}\left(X_{r}^{\max }\right)
$$

- The procedure can be repeated back-tracking to the leaves, retrieving maximal values for all variables

## Example for linear chain

$$
\begin{aligned}
X_{N}^{\max } & =\underset{X_{N}}{\operatorname{argmax}} \mu_{f_{N-1, N} \rightarrow X_{N}}\left(X_{N}\right) \\
X_{N-1}^{\max } & =\phi_{f_{N-1, N} \rightarrow X_{N}}\left(X_{N}^{\max }\right) \\
X_{N-2}^{\max } & =\phi_{f_{N-2, N-1} \rightarrow X_{N-1}}\left(X_{N-1}^{\max }\right) \\
\vdots & \\
X_{1}^{\max } & =\phi_{f_{1,2} \rightarrow X_{2}}\left(X_{2}^{\max }\right)
\end{aligned}
$$

## Recoving maximal configuration

Trellis for linear chain

- A trellis or lattice diagram shows the $K$ possible states of each variable $X_{n}$ one per row
- For each state $k$ of a variable $X_{n}, \phi_{f_{n-1, n} \rightarrow X_{n}}\left(X_{n}\right)$ defines a unique (maximal) previous state, linked by an edge in the diagram
- Once the maximal state for the last variable $X_{N}$ is chosen, the maximal states for other variables are recovering following the edges backward.

## Inference

## Underflow issues

- The max-product algorithm relies on products (no summation)
- Products of many small probabilities can lead to underflow problems
- This can be addressed computing the logarithm of the probability instead
- The logarithm is monotonic, thus the proper maximal configuration is recovered:

$$
\log \left(\max _{\mathbf{X}} p(\mathbf{X})\right)=\max _{\mathbf{X}} \log p(\mathbf{X})
$$

- The effect is replacing products with sums (of logs) in the max-product algorithm, giving the max-sum one

## Inference

## Exact inference on general graphs

- The sum-product and max-product algorithms can be applied to tree-structured graphs
- Many applications require graphs with (undirected) loops
- An extension of this algorithms to generic graphs can be achieved with the junction tree algorithm
- The algorithm does not work on factor graphs, but on junction trees, tree-structured graphs with nodes containing clusters of variables of the original graph
- A message passing scheme analogous to the sum-product and max-product algorithms is run on the junction tree

## Problem

- The complexity on the algorithm is exponential on the maximal number of variables in a cluster, making it intractable for large complex graphs.

## Inference

## Approximate inference

- In cases in which exact inference is intractable, we resort to approximate inference techniques
- A number of techniques for approximate inference exist: loopy belief propagation message passing on the original graph even if it contains loops variational methods deterministic approximations, assuming the posterior probability (given the evidence) factorizes in a particular way sampling methods approximate posterior is obtained sampling from the network

## Inference

## Loopy belief propagation

- Apply sum-product algorithm even if it is not guaranteed to provide an exact solution
- We assume all nodes are in condition of sending messages (i.e. they already received a constant 1 message from all neighbours)
- A message passing schedule is chosen in order to decide which nodes start sending messages (e.g. flooding, all nodes send messages in all directions at each time step)
- Information flows many times around the graph (because of the loops), each message on a link replaces the previous one and is only based on the most recent messages received from the other neighbours
- The algorithm can eventually converge (no more changes in messages passing through any link) depending on the specific model over which it is applied

## Approximate inference

## Sampling methods

- Given the joint probability distribution $p(\boldsymbol{X})$
- A sample from the distribution is an instantiation of all the variables $\boldsymbol{X}$ according to the probability $p$.
- Samples can be used to approximate the probability of a certain assignment $\boldsymbol{Y}=\mathbf{y}$ for a subset $\boldsymbol{Y} \subset \boldsymbol{X}$ of the variables:
- We simply count the fraction of samples which are consistent with the desired assignment
- We usually need to sample from a posterior distribution given some evidence $\boldsymbol{E}=\mathbf{e}$

## Sampling methods

## Markov Chain Monte Carlo (MCMC)

- We usually cannot directly sample from the posterior distribution (too expensive)
- We can instead build a random process which gradually samples from distributions closer and closer to the posterior
- The state of the process is an instantiation of all the variables
- The process can be seen as randomly traversing the graph of states moving from one state to another with a certain probability.
- After enough time, the probability of being in any particular state is the desired posterior.
- The random process is a Markov Chain

## Appendix: Sampling methods

## Note

- The state graph is very different from the graphical model of the joint distribution:
- nodes in the graphical model are variables
- nodes in the state graph are instantiations of all the variables

## Markov chain

## Definition

- A Markov chain consists of:
- A space $\operatorname{Val}(\boldsymbol{X})$ of possible states (one for each possible instantiation of all variables $\boldsymbol{X}$ )
- A transition probability mode/ defining for each state $\boldsymbol{x} \in \operatorname{Val}(\boldsymbol{X})$ a next-state distribution over $\operatorname{Val}(\boldsymbol{X})$. We will represent the transition probability from state $\mathbf{x}$ to $\mathbf{x}^{\prime}$ as:

$$
\mathcal{T}\left(\mathbf{x} \rightarrow \mathbf{x}^{\prime}\right)
$$

- A Markov chain defines a stochastic process that evolves from state to state

## Markov chain

## Homogeneous chains

- A Markov chain is homogeneous if its transition probability model does not change over time
- Transition probabilities between states do not depend on the particular time instant in the process
- We will be interested in such chains for sampling

## Markov chain

## Chain dynamics

- Consider a sequence of states $\mathbf{x}^{(0)}, \mathbf{x}^{(1)}, \mathbf{x}^{(2)}, \ldots$ of the random process
- Being random, the state of the process at time $t$ can be seen as a random variable $\boldsymbol{X}^{(t)}$
- Assume the initial state $\boldsymbol{X}^{(0)}$ is distributed according to some initial probability $p^{(0)}\left(\boldsymbol{X}^{(0)}\right)$
- The distribution over subsequent states can be defined using the chain dynamics as:

$$
p^{(t+1)}\left(\boldsymbol{X}^{(t+1)}=\mathbf{x}^{\prime}\right)=\sum_{\mathbf{x} \in \operatorname{Val}(\boldsymbol{X})} p^{(t)}\left(\boldsymbol{X}^{(t)}=\mathbf{x}\right) \mathcal{T}\left(\mathbf{x} \rightarrow \mathbf{x}^{\prime}\right)
$$

- The probability of being in a certain state $\mathbf{x}$ at time $t$ is the sum of the probabilities of being in any possible state $\mathbf{x}^{\prime}$ at time $t-1$ times the probability of a transition from $\mathbf{x}^{\prime}$ to $\mathbf{x}$

## Markov chain

## Convergence

- As the process converges, we expect that $p^{(t+1)}$ becomes close to $p^{(t)}$ :

$$
p^{(t)}\left(\mathbf{x}^{\prime}\right) \approx p^{(t+1)}\left(\mathbf{x}^{\prime}\right)=\sum_{\mathbf{x} \in \operatorname{Val}(\boldsymbol{X})} p^{(t)}(\mathbf{x}) \mathcal{T}\left(\mathbf{x} \rightarrow \mathbf{x}^{\prime}\right)
$$

- At convergence, we expect to have reached an equilibrium distribution $\pi(\boldsymbol{X})$ :
- The probability of being in a state is the same as that of transitioning into it from a random predecessor

## Markov chain

## Stationary distribution

- A distribution $\pi(\boldsymbol{X})$ is a stationary distribution for a Markov Chain $\mathcal{T}$ if:

$$
\pi\left(\boldsymbol{X}=\mathbf{x}^{\prime}\right)=\sum_{\mathbf{x} \in \operatorname{Val}(\boldsymbol{X})} \pi(\boldsymbol{X}=\mathbf{x}) \mathcal{T}\left(\mathbf{x} \rightarrow \mathbf{x}^{\prime}\right)
$$

## Requirements

- We are interested in Markov Chains with:
- a unique stationary distribution
- which is reachable from any starting distribution $p^{(0)}$
- There are various conditions to guarantee this property (e.g. ergodicity)
- For a Markov Chain with a finite state space $\operatorname{Val}(\boldsymbol{X})$, regularity is a sufficient and necessary condition

## Markov chain

## Regular chains

A Markov chain is regular if there exists a number $k$ such that for all state pairs $\mathbf{x}, \mathbf{x}^{\prime} \in \operatorname{Val}(\boldsymbol{X})$ the probability of getting from $\mathbf{x}$ to $\mathbf{x}^{\prime}$ in exactly $k$ steps is greater than zero

Conditions ensuring regularity

- It is possible to get from any state to any other state using a positive probability path in the state graph
- For every state $\mathbf{x}$ there is a positive probability of transitioning from $\mathbf{x}$ to $\mathbf{x}$ in one step (self loop)

## Markov chain

## Markov chains for graphical models

- The typical use is estimating the probability of a certain instantiation $\mathbf{x}$ of the variables $\boldsymbol{X}$ given some evidence $E=\mathbf{e}$
- This requires sampling from the posterior distribution $p(\boldsymbol{X} \mid \boldsymbol{E}=\mathbf{e})$
- We wish to define a chain for which $p(\boldsymbol{X} \mid \boldsymbol{E}=\mathbf{e})$ is the stationary distribution
- States in the chain should be the subset of all possible instantiations which is consistent with the evidence $\mathbf{e}$ :

$$
\mathbf{x} \in \operatorname{val}(\boldsymbol{X}) \text { s.t. } \mathbf{x}_{\boldsymbol{E}}=\mathbf{e}
$$

## Markov chain

## Transition model

- A simple transition model consists of updating variables in $\hat{\boldsymbol{X}}=\boldsymbol{X}-\boldsymbol{E}$ one at a time
- This can be seen as made of a set of $k=|\hat{\boldsymbol{X}}|$ local transition models $\mathcal{T}_{i}$, one for each variable $X_{i} \in \hat{\boldsymbol{X}}$
- Let $\boldsymbol{U}_{i}=\boldsymbol{X}-X_{i}$ and $\mathbf{u}_{i}$ a possible instantiation of $\boldsymbol{U}_{i}$
- The local transition model $\mathcal{T}_{i}$ defines transitions between states $\left(\mathbf{u}_{i}, x_{i}\right)$ and $\left(\mathbf{u}_{i}, x_{i}^{\prime}\right)$
- By defining a transition as a sequence of $k$ local transitions, one for each variable $X_{i}$, we obtain a homogeneous (i.e. not time-dependent) global transition model

## Markov chain

## Gibbs Sampling

- Gibbs sampling is an efficient and effective simple Markov chain for factored state spaces (like the ones in graphical models)
- Local transitions $\mathcal{T}_{i}$ are defined "forgetting" about the value of $X_{i}$ in the current state.
- This allows to sample a new value according to the posterior probability of $X_{i}$ given the rest of the current state:

$$
\mathcal{T}_{i}\left(\left(\mathbf{u}_{i}, x_{i}\right) \rightarrow\left(\mathbf{u}_{i}, x_{i}^{\prime}\right)\right)=p\left(x_{i}^{\prime} \mid \mathbf{u}_{i}\right)
$$

- The Gibbs chain samples a new state performing $k$ subsequent local moves
- We only take samples after a full round of local moves

## Gibbs Sampling

## Regularity of Gibbs chains

- Gibbs chains are ensured to be regular if the distribution is strictly positive: every value of $X_{i}$ given any instantiation of $\boldsymbol{U}_{i}$ has non-zero probability
- In this case we can get from any state to any state in at most $k=|\hat{\boldsymbol{X}}|$ local steps
- Gibbs chains have the desired posterior $p(\boldsymbol{X} \mid \boldsymbol{E}=\mathbf{e})$ as stationary distribution

## Positivity

- Positivity of the distributions is guaranteed if no conditional probability distribution (for BN) or clique potential (for MN) has zero value for any configuration of the variables

## Gibbs Sampling

## Computing local transition probabilities

- Local transition probabilities can be computed very efficiently for discrete graphical models.
- Only the Markov blanket of $X_{i}$ is needed in order to compute its posterior $p\left(X_{i} \mid \mathbf{u}_{i}\right)$

## Gibbs Sampling

## Generating samples

- In order to generate samples from the correct posterior distribution, we need to wait until the Markov chain has converged to the stationary distribution
- Once at convergence, all subsequent samples could be used to estimate the desired probability
- However, consecutive samples are definitely not independent
- A possible approach consists of letting an interval of $d$ samples before collecting the next sample
- In practice it is often the case that using all samples leads to better estimates if a fixed amount of time is provided (simply because they are based on more even if less independent samples)

## Gibbs Sampling

## Limitations

- It requires posterior $p\left(X_{i} \mid \mathbf{u}_{i}\right)$ to be efficiently computable (this can be difficult in e.g. continuous models)
- The transition model produces very incremental "local" moves, mixing time for convergence of the chain can be very long.

## Metropolis-Hastings

## In a nutshell

- Generate next state according to an easy to compute proposal distribution
- Decide whether to accept the move or stay in the previous state according to an acceptance probability that accounts for the difference between proposal and target distribution

## Note

- Depending on the proposal distribution, it can move in the space much faster than Gibbs Sampling
- Gibbs Sampling is a special case of Metropolis Hastings for a particular choice of the proposal distribution

## Metropolis-Hastings

## Reversible chains

A finite-state Markov chain $\mathcal{T}$ is reversible if there exists a unique distribution $\pi$ such that, for all $\mathbf{x}, \mathbf{x}^{\prime} \in \operatorname{Val}(\boldsymbol{X})$ :

$$
\pi(\mathbf{x}) \mathcal{T}\left(\mathbf{x} \rightarrow \mathbf{x}^{\prime}\right)=\pi\left(\mathbf{x}^{\prime}\right) \mathcal{T}\left(\mathbf{x}^{\prime} \rightarrow \mathbf{x}\right)
$$

The equation is called detailed balance

## Note

This means that if we start sampling a state using $\pi$ and move according to $\mathcal{T}$, the probability of going from $\mathbf{x}$ to $\mathbf{x}^{\prime}$ is the same as the one of going from $\mathbf{x}^{\prime}$ to $\mathbf{x}$.

## Metropolis-Hastings

## Regular reversible chains

If a regular Markov chain $\mathcal{T}$ satisfies the detailed balance equation relative to $\pi$, then $\pi$ is its unique stationary distribution.

## Constructive approach

Metropolis-Hastings is a constructive approach where we choose a proposal distribution and select the acceptance probabilities allowing to obtain the target distribution as the stationary one.

## Metropolis-Hastings

## Proposal distribution

- An arbitrary distribution $\mathcal{T}^{Q}$ inducing a regular chain.
- E.g., sequence of local transition models $\mathcal{T}_{i}^{Q}$ each sampling from a uniform distribution over the values of $X_{i}$.

## Transition model

- Let $\mathcal{T}^{Q}$ be the proposal distribution
- Let $\mathcal{A}\left(\mathbf{x} \rightarrow \mathbf{x}^{\prime}\right)$ be the acceptance probability.
- The resulting transition model is:

$$
\begin{aligned}
\mathcal{T}\left(\mathbf{x} \rightarrow \mathbf{x}^{\prime}\right) & =\mathcal{T}^{Q}\left(\mathbf{x} \rightarrow \mathbf{x}^{\prime}\right) \mathcal{A}\left(\mathbf{x} \rightarrow \mathbf{x}^{\prime}\right) \quad \text { if } \mathbf{x} \neq \mathbf{x}^{\prime} \\
\mathcal{T}(\mathbf{x} \rightarrow \mathbf{x}) & =\mathcal{T}^{Q}(\mathbf{x} \rightarrow \mathbf{x})+\sum_{\mathbf{x} \neq \mathbf{x}^{\prime}} \mathcal{T}^{Q}\left(\mathbf{x} \rightarrow \mathbf{x}^{\prime}\right)\left(1-\mathcal{A}\left(\mathbf{x} \rightarrow \mathbf{x}^{\prime}\right)\right)
\end{aligned}
$$

## Metropolis-Hastings

## Acceptance probability

- The acceptance probability should be chosen so that the detailed balance equation holds for the target distribution $\pi$ :

$$
\pi(\mathbf{x}) \mathcal{T}^{Q}\left(\mathbf{x} \rightarrow \mathbf{x}^{\prime}\right) \mathcal{A}\left(\mathbf{x} \rightarrow \mathbf{x}^{\prime}\right)=\pi\left(\mathbf{x}^{\prime}\right) \mathcal{T}^{Q}\left(\mathbf{x}^{\prime} \rightarrow \mathbf{x}\right) \mathcal{A}\left(\mathbf{x}^{\prime} \rightarrow \mathbf{x}\right)
$$

- This is achieved by the following acceptance probability:

$$
\mathcal{A}\left(\mathbf{x} \rightarrow \mathbf{x}^{\prime}\right)=\min \left(1, \frac{\pi\left(\mathbf{x}^{\prime}\right) \mathcal{T}^{Q}\left(\mathbf{x}^{\prime} \rightarrow \mathbf{x}\right)}{\pi(\mathbf{x}) \mathcal{T}^{Q}\left(\mathbf{x} \rightarrow \mathbf{x}^{\prime}\right)}\right)
$$

## Metropolis-Hastings

## Mixing time

- The mixing time is the time a chain takes to converge to its stationary distribution
- The mixing time depends on how connected the state space is
- There is no general-purpose theoretical analysis for the mixing time of graphical models.
- A practical solution comes from the observation that multiple chains sampling the same distribution should yield similar estimates upon convergence

## Metropolis-Hastings

How to check convergence (1)

- Run $K$ independent chains with different starting points in parallel
- Discard the first $T$ samples from each chain
- Let $\boldsymbol{X}_{k}[m]$ be a sample from chain $k$ after $T+m$ iterations, and $f$ be an arbitrary function on the samples (e.g. probability of a certain node taking a certain value)
- Let

$$
\bar{f}_{k}=\frac{1}{M} \sum_{m=1}^{M} f\left(\boldsymbol{X}_{k}[m]\right)
$$

- and

$$
\bar{f}=\frac{1}{K} \sum_{k=1}^{K} \bar{f}_{k}
$$

## Metropolis-Hastings

How to check convergence (2)

- The between chain variance of $f$ is:

$$
B=\frac{M}{K-1} \sum_{k=1}^{K}\left(\bar{f}_{k}-\bar{f}\right)^{2}
$$

- The within chain variance of $f$ is:

$$
W=\frac{1}{K} \frac{1}{M-1} \sum_{k=1}^{K} \sum_{m=1}^{M}\left(f\left(\boldsymbol{X}_{k}[m]-\bar{f}_{k}\right)^{2}\right.
$$

## Metropolis-Hastings

How to check convergence (3)

- A measure of disagreement between chains is given by:

$$
\hat{R}=\sqrt{\frac{V}{W}}
$$

where $V=\frac{M-1}{M} W+\frac{1}{M} B$ is an overestimate of the variance of our estimate of $f$ based on the collected samples.

- We can stop when $\hat{R} \approx 1$
- For further confidence (all chains could have converged to the same mode..) we can try different indicator functions $f$.
